We investigate the quantum recoil force acting on an excited atom close to the surface of a nonreciprocal photonic topological insulator (PTI). The main atomic emission channel is the unidirectional surface plasmon propagating at the PTI-vacuum interface, and we show that it enables a spontaneous lateral recoil force that scales at short distances as 1/d4, where d is the atom-PTI separation. Remarkably, the sign of the recoil force is polarization and orientation independent, and it occurs in a translation-invariant homogeneous system in thermal equilibrium. Surprisingly, the recoil force persists for very small values of the gyration pseudovector, which, for a biased plasma, corresponds to very low cyclotron frequencies. The ultrastrong recoil force is rooted in the quasihyperbolic dispersion of the surface plasmons. We consider both an initially excited atom and a continuous pump scenario, the latter giving rise to a steady lateral force whose direction can be changed at will by simply varying the orientation of the biasing magnetic field. Our predictions may be tested in experiments with cold Rydberg atoms and superconducting qubits.

DOI: 10.1103/PhysRevB.97.201108

The force on neutral atoms or nanoparticles due to electromagnetic fields is an important tool in atomic control and manipulation (e.g., in optical trapping for ultracold gases [1–3], optical tweezers [4,5], etc.). Fluctuations of the electromagnetic field, of both quantum and thermal origin, play an important role in this context. They explain the presence of the Casimir-Polder forces acting on atoms located close to the surface of a body [6,7]. For planar surfaces the Casimir-Polder force is along the normal direction and can be either attractive or repulsive [8–13]. The normal component of the force has been extensively investigated both theoretically and experimentally (see Ref. [14] and references therein).

For excited systems (e.g., an excited or driven atom) it is also possible to have nonzero lateral forces, even when the material surface is smooth and translation invariant. Such lateral forces have been studied both in classical and in quantum scenarios, e.g., when a polarizable nanoparticle is near an anisotropic substrate with a tilted axis [15], when linearly polarized light illuminates a chiral particle [16], when the emitter has circular polarization [17,18], or in moving systems [19,20]. These studies reveal interesting possibilities to tune and sculpt the surface-atom interactions.

The discovery of topological light states is perhaps the most exciting development in photonics in recent years. Starting with the seminal studies of Haldane and Raghu [21,22], it has been shown that some nonreciprocal photonic platforms are inherently topological [23–25], and thereby may enable the propagation of unidirectional topologically protected and scattering-immune edge states. More recently, it has been shown that the concepts of topological photonics can be extended to electromagnetic continua, with no intrinsic periodicity [26–31]. The consequences of topological properties in the context of quantum optics have been little explored, with a few exceptions [32–34].

In this Rapid Communication, we investigate a mechanism that enables a lateral recoil force due to the spontaneous emission features of atoms close to a photonic topological insulator (PTI) surface. In an environment invariant along the j-coordinate axis, the lateral quantum recoil force Fj associated with a spontaneous decay process generally vanishes since the emission occurs in random directions. For particular polarizations of the emitter (e.g., circular polarization), the lateral force may be nonzero due to the interference of the dipole and its image [18,35]. However, in systems formed by reciprocal media, the sign of the lateral force is invariably polarization dependent [18,35].

In contrast, here we demonstrate that the PTI’s unidirectional light states create the opportunity for unusual optical manipulations of two-level quantum systems with a strongly asymmetric, and tunable, lateral optical force in a laterally invariant environment, with the sign of the force independent of the polarization state and of the atom orientation.

We first consider a two-level system (called the “atom” in the following) in a general inhomogeneous environment. In the dipole approximation, the optical force operator is \( \hat{F}_i = \hat{p} \cdot \partial_i \hat{E} \), \( i = x, y, z \) [5]. The hat indicates that the relevant quantity...
represents a quantum operator. Here, $\hat{p}$ is the electric dipole operator for the two-level atom. By solving the Heisenberg equations with the Markov approximation, it is possible to show that the expectation of the optical force is given by [36]

$$F(t) = \langle \hat{F}_r \rangle = \rho_{ee}(t)F_{R,i} + [1 - 2\rho_{ee}(t)]F_{C,i}$$

(1)

with $\rho_{ee}(t)$ representing the probability of the atom being in the excited state,

$$F_{R,i} = 2 \text{Re}\left\{ \tilde{\gamma}^* \cdot [-i\omega \partial_t \mathbf{G}(\mathbf{r}, \mathbf{r}_0; \omega)] \right\}_{\omega = \omega_0 + i\delta}$$

(2)

is the resonant component of the force, and $\partial_i = \hat{u}_i \cdot \nabla_r$. Here, $\omega_0$ is the atomic transition frequency, $\tilde{\gamma} = [\gamma_+ 0 0]^T$ is a six-vector, and $\gamma$ is the dipole matrix element. Moreover, $F_C = -\nabla_r \epsilon_C$ is the usual Casimir-Polder force for the ground state [36], which vanishes for planar surfaces along laterally invariant directions.

The force is written in terms of the system Green’s function $\mathbf{G}(\mathbf{r}, \mathbf{r}_0; \omega)$ (a $6 \times 6$ tensor), defined in the companion article [36], with $\mathbf{r}_0$ the position of the atom. Only the scattering part of the Green’s function needs to be considered, because by symmetry the self-field does not contribute to the force [36]. For simplicity, we neglect the effect of thermal photons, which is acceptable when $h\omega_0$ is higher than the average thermal photon energy $k_B T \ll h\omega_0$ and when $d \ll \lambda_T$, with $\lambda_T = h c / k_B T$ the thermal wavelength and $d$ the distance between the atom and the macroscopic body. Equation (1) generalizes the theory of Refs. [37,38] to arbitrary reciprocal or nonreciprocal and possibly biaxiosotropic systems.

Next, we turn to the geometry of interest, a $z$-stratified electromagnetic environment, invariant to translations along the $\alpha = x, y$ directions. Since the lateral force due to the zero-point energy fluctuations vanishes, $\mathbf{F}_{C,\alpha} = 0$, the lateral force is determined uniquely by the resonant term $F_{\alpha}(t) = \rho_{ee}(t)\mathbf{F}_{R,\alpha}$. We prove in Ref. [36] that in the limit of vanishing material loss, $\mathbf{F}_{R,\alpha}$ can be written in terms of the electromagnetic modes $\mathbf{F}_{n\mathbf{k}}$ of the environment as

$$\mathbf{F}_{R,\alpha} = \text{Re}\left( i \pi \sum_{\omega_{n\mathbf{k}}} \omega_{n\mathbf{k}} \tilde{\gamma}^* \cdot \partial_{\alpha} \mathbf{F}_{n\mathbf{k}} \otimes \mathbf{F}_{n\mathbf{k}}^\dagger \cdot \hat{\delta}(\omega_{n\mathbf{k}} - \omega_0) \right).$$

(3)

where $\mathbf{F}_{n\mathbf{k}} = (\mathbf{F}_{n\mathbf{k}} \cdot \mathbf{H}_{n\mathbf{k}})^T$ and $\omega_{n\mathbf{k}}$ is the oscillation frequency of the mode $n\mathbf{k}$. The above result fully takes into account material dispersion. In the following, we consider the recoil force on an atom in vacuum close to the interface with a topological material, e.g., a gyrotropic medium [28–30,32,39], as shown in Fig. 1(a).

As an example, we suppose the region $z > 0$ is a vacuum, and that the region $z < 0$ is filled with a gyrotropic material with permittivity

$$\epsilon = \epsilon_0 (\epsilon_x \mathbf{I} + \epsilon_y \hat{y} \hat{y} + i \epsilon_z \hat{z} \times \mathbf{I}),$$

(4)

where $\mathbf{I} = \mathbf{I} - \hat{y} \hat{y}$, with $\epsilon_x$ being the magnitude of the gyration pseudovector. For the gyrotropic medium we consider a magnetized plasma (e.g., InSb [40,41]). For a static bias magnetic field along the $+y$ axis, the permittivity components are [42]

$$\epsilon_x = 1 - \omega_p^2 (1 + i \Gamma / \omega) / (\omega + i \Gamma)^2 - \omega_c^2,$$

$$\epsilon_y = 1 - \omega_p^2 / (\omega + i \Gamma)^2, \quad \epsilon_z = \frac{1}{\omega^2} - \omega_c^2 / (\omega + i \Gamma)^2.$$ (5)

Here, $\omega_p$ is the plasma frequency, $\Gamma$ is the collision rate associated with damping (taken to be $\Gamma = 0.015 \omega_p$), $\omega_c = -q B_0 / m > 0$ is the cyclotron frequency, $q = -e$ is the electron charge, $m$ is the electron effective mass, and $B_0$ is the static bias.

In the quasistatic lossless limit, the natural modes have an electrostatic nature $\mathbf{F}_{n\mathbf{k}} \approx [-\nabla \phi_{n\mathbf{k}} 0]^T$, and are surface plasmon polariton (SPP) waves. In Ref. [36], it is shown that the SPP resonances have the dispersion $\omega_{n\mathbf{k}} = \omega_{0\mathbf{k}} = \omega_{0\mathbf{k}}^\text{rem} + 2 \omega_{0\mathbf{k}}^\text{rem} [1 + \sin^2(\theta)]$. Here, $\theta$ represents the angle of the SPP wave vector $\mathbf{k}$ (parallel to the interface) and the $x$ axis. In general, we have $\omega_{0\mathbf{k}} < \omega_{0\mathbf{k}} < \omega_{n\mathbf{k}}$ with $\omega_{n\mathbf{k}} = \omega_{0\mathbf{k}} / \sqrt{1 + \sin^2(\theta)}$. The quasistatic solution describes the resonant SPP waves with large $\mathbf{k}$, which are the most influential for the light-matter interactions. Different from the unbiased case ($\omega_c = 0$), for which the SPP resonance is direction independent, $\omega_p = \omega_{0\mathbf{k}} / \sqrt{2} \equiv \omega_{p\text{app}}$, for a biased plasma the emitted plasmons are launched along preferred directions of space (see Fig. 1(a), and Fig. 2(a), which shows the angle of the SPP wave vector $\mathbf{k}$; a further discussion of the angular dependence of the SPP is provided in Ref. [36]). Intuitively one may expect that the sign of the optical force $\mathbf{F}_r$ is contrary to the $(x)$ component of the wave vector of the SPPs excited by the atom, i.e., the SPPs that satisfy $\omega_{n\mathbf{k}} = \omega_{0\mathbf{k}}$.

This heuristic argument is confirmed by a detailed calculation of the force (3) that gives $F_x = F_{0x} \mathbf{F}_x (x = x, y)$, with $F_{0x} = 3|\gamma|^2 / (16 \pi d^4 \epsilon_0)$ a normalizing factor, and $\mathbf{F}_x$ a
with the force existing primarily in the frequency interval $\omega_c < \omega_p$, the force can be controlled by changing the magnetic bias strength, and that the recoil force is largest for $\omega_0 = \omega_\perp$, denoted by the vertical dashed lines in the figure. Both effects can be understood from conservation of momentum; the angle of the SPP wave vector $\mathbf{k}$ (the main emission channel) is shown in Fig. 2(a), where it can be seen that for $\omega_0 = \omega_\perp$, $\theta_0 = 180^\circ$ ($-x$ direction), resulting in a positive lateral force along $x$, whereas for $\omega_0 = \omega_\|$, $\theta_0 = 0^\circ$ ($+x$ direction), leading to a negative lateral force. Similarly, the recoil force will be largest for $\omega_0 = \omega_\perp$, since $F_x$ is maximized when the emitted SPP is along the $\pm x$ axis.

A further aspect of the SPPs is that they form beamlike far-field patterns due to the hyperbolic nature of the material. Figure 3 shows the SPP equifrequency contour (EFC) for the case of $\omega_0/\omega_p = 0.7$ for various values of $\omega_c/\omega_p$. For
an anisotropic medium the energy flow direction defined by the group velocity $\mathbf{v}_k \omega_k$ (orthogonal to the equifrequency contour) does not necessarily coincide with the direction of the plasmon wave vector $k = (k_x, k_y, 0)$. For the case of $\omega_c/\omega_p = 0$ (nonbimodal plasma), the EFC is a circle, such that at each point $(k_x, k_y)$ on the EFC the flow of energy is along the direction normal to the circle, and thereby the SPP emission is omnidirectional when $\gamma = \tilde{y}\tilde{z}$.

For a very weak value of the bias [Fig. 3(a)], the circle becomes slightly elongated along the $k_x$ axis. For a larger bias the circle opens up [Fig. 3(b)], and as the bias is increased further, the EFC become hyperbolic-like in the range $\omega_0 < \omega < \omega_s$, leading to a unidirectional (nonreciprocal) SPP beam with energy flow indicated by the red arrow in Fig. 3(c). The SPP far-field pattern at two values of bias is shown in Fig. 3(d), where it can be seen that the SPP forms two narrow beams. The Poynting vector of the short-wavelength SPPs is always directed towards the narrow beams. The Poynting vector of the short-wavelength interval $\omega_0/2 < \omega < \omega_0$ is always directed towards the narrow beams. The Poynting vector of the short-wavelength $\omega_0$ interval $\omega_0/2 < \omega < \omega_0$ is always directed towards the narrow beams.

Figure 4 shows the EFC of the corresponding SPP for $\omega_0 = \omega_{\text{app}}$ [see, e.g., Fig. 2(a)], showing that for each $\omega_0$ there is an optimal value for the bias (vertical dashed line) that maximizes the recoil force $|\rho_{ee}(\omega_0)\omega_{\text{app}}|$. As $\omega_0 \to \omega_{\text{app}}$ an ultrastrong recoil force is obtained for very small bias, as shown in detail in Fig. 2(b).

In order to understand the phenomenon of strong force with small bias, it can be observed that as the bias field approaches zero, the SPP frequency span $\omega_0 < \omega < \omega$ becomes narrower and narrower, as $\omega_0$ and $\omega_0$ approach $\omega_{\text{app}}$ [see, e.g., Fig. 2(a)], the point at which the two bright lines in Fig. 1(c) intersect. Figure 4 shows the EFC of the corresponding SPP for $\omega_0 = \omega_{\text{app}}$ for small plasma bias. For small bias the EFC hyperbola branches became aligned along the $k_x$ axis [Fig. 4(a)]. In particular, for Fig. 4(a) there is a wide spectral region near the center of the EFC (roughly $|k_x|/k_0 < 10$), for which $k_x \neq 0$, and a strong force contribution exists. Thus, the ultrastrong force at a weak bias is due to the high density of states determined by the hyperbolic EFC.

Further support for a strong recoil force at low bias when $|\omega_0 - \omega_{\text{app}}|$ comes from the quasistatic solution (6); in the limit of no bias, it can be shown that $|\omega_0 - \omega_{\text{app}} + \omega_s/2 \cos \theta|$ and $\omega_0 \to 1/2$. Then, for a $z$-polarized atom (1$^+_{\theta,\theta} = 1$), (6) becomes

$$\tilde{F}_x = -\rho_{ee}(\omega_{\text{app}}) \omega_{\text{app}} \frac{\omega_0 - \omega_{\text{app}}}{\sqrt{(\omega_s/2)^2 - (\omega_0 - \omega_{\text{app}})^2}}.$$  \hspace{1cm} (7)

Therefore, the quasistatic force diverges when $|\omega_0 - \omega_{\text{app}}| = |\omega_s/2|$, i.e., when the atomic transition frequency matches $\omega_s$. Although material absorption ensures that the exact force is finite, the divergence of the quasistatic result indicates a strong force persisting as $\omega_0 \to 0$. However, below a critical bias value [Fig. 4(b)], the system tends towards isotropic (i.e., $\epsilon_g \ll \epsilon_s$), the interface does not support SPP modes, and the force becomes weak.

Although the presented results apply to the plasma dispersion (4), for a more complicated plasma model, e.g., InSb [40], which includes phonon contributions, the same qualitative behavior is found, although the quasistatic analysis does not lead to simple closed-form expressions. Furthermore, an interface with any Chern-type periodic photonic topological insulator would provide a net spontaneous recoil force due to the unidirectionality of the SPP.

In the absence of an external excitation, the spontaneous emission depopulates the atom, leading to zero steady-state force. To achieve a steady recoil force, the atom can be pumped by a laser. Starting with the master equation for a general nonreciprocal, lossy, and inhomogeneous environment, the atomic population is [43]

$$\rho_{ee}(t) = \frac{2\Omega^2}{\lambda_1 \lambda_2} + \frac{\lambda_3 (\lambda_1 + 1/2) + 2\Delta^2}{\lambda_1 (\lambda_1 - \lambda_2)} e^{i\Delta t} + \frac{\lambda_2 (\lambda_2 + 1/2) + 2\Delta^2}{\lambda_2 (\lambda_2 - \lambda_1)} e^{i\Delta t},$$ \hspace{1cm} (8)

where $\Omega = \Omega/\Gamma$, with $\Omega = \gamma \cdot E/\hbar$ the Rabi frequency and $\Gamma$ the decay rate, $\Gamma = \Gamma_0$, and where $\lambda_1, \lambda_2 = (3/2 \pm \sqrt{1/4 - 16\Omega^2})$. Under steady-state conditions $t \to \infty$, $\rho_{ee,ss} = 4\Omega^2/(1 + 8\Omega^2)$.

Figure 5 shows the normalized force $\tilde{F}_x = \mathcal{F}_{x,R}(t)/\mathcal{F}_0$ as a function time for different laser intensities. When $\Omega^2/\Gamma = 0$ the force decays to zero, whereas for the pumped cases a nonzero steady-state force exists. The laser can be applied orthogonal to the $x$ axis, so as not to influence the net lateral force.

To provide a quantitative estimate of the recoil force, the normalization constant $\mathcal{F}_0 = 0.075 \text{pN} (\tilde{D}/d^4)$, where $\tilde{D}$ is the dipole moment in debye and $d$ is the atom-interface distance in nm. For example, for a Rydberg atom [50] having $\gamma = 7900 \text{D}$ located 100 nm above the substrate, $\mathcal{F}_0 = 0.047 \text{pN}$. Alternatively, a superconducting qubit [51] attached to a cantilever could be used to detect the force. One possible implementation of the plasma is InSb, where $\omega_p/(2\pi) \approx 5 \text{THz}$ for the samples measured in Ref. [40], and $\omega_0/(2\pi)$ ranges from 1 to 6 THz for magnetic bias 1–5 T, respectively.
emerges in a homogeneous system in a thermal equilibrium, and its sign is independent of the atom polarization and orientation. In order to understand the behavior of the recoil force, the SPPs guided by the interface of the topological medium and vacuum have been investigated. Due to the quasi-hyperbolic nature of the PTI, the SPPs emitted by an excited atom form narrow beams, whose direction is dependent on the atomic transition frequency. The force is maximized at certain atomic transition frequencies, and persists down to very small bias values due to the high density of photonic states. To achieve a steady recoil force, the quantum dynamics of the atom has been studied by solving the relevant master equation for a laser-pumped system.
